

Imaging the Structure of Thin Films: Brewster Angle Microscopy

A Brewster angle microscope (BAM) enables the visualization of Langmuir monolayers and adsorbate films at the air-water interface. The images aid in understanding both the structure and flow behavior of monolayer materials.

Brewster angle microscopy

When a light beam hits a surface, it usually reflects from it. If a p-polarized light beam is directed at a clean surface at a unique angle, no reflection occurs. If the properties of the interface change, reflection will occur. This behaviour is explained by Brewster's law which describes the use of the Brewster angle (α) for a particular optical media with a refractive index of n . The principle of using the Brewster angle to obtain an image of a monolayer on water substrate is illustrated in Figure 1.

[Figure 1]: The principle of Brewster angle microscopy.

Brewster angle microscopy was first introduced in 1991 [1,2]. Since its introduction, it has become the standard technique for the imaging of thin films on liquid surfaces. When combined with a Langmuir trough, the method can be used to relate the BAM images with characteristic phase transition points in a Langmuir isotherm. This gives valuable information on the formation dynamics of the monolayer.

Key application areas

Lipid monolayers and molecular interactions. Langmuir films of lipid monolayers are often used as model structures of cell membranes. Brewster angle microscopy images at characteristic phase transitions of the surface pressure - area isotherm give valuable information on the structural and orientational changes in the monolayer. The published data includes BAM images of molecular interactions, lipids in different ionic environments and nanoparticle interactions [3-6]. Since BAM allows for direct observation of lipid monolayers during compression, it is especially valuable in the imaging of tear fluids and biological liquids [7].

Polymer and nanoparticle monolayers. The Langmuir technique has been shown to be an effective way for fabricating single-particle thick layers of lipids, polymers and nanoparticles on liquid surfaces. A Langmuir film can be transferred onto the desired substrate, creating new possibilities for fabricating nanoscale layers and functional surfaces on various materials. Recently, Brewster angle microscopy has been used for finding the optimized transfer conditions of metal nanoparticles and graphene oxide [8,9].

Petroleum industry. There is an increased interest in understanding the properties and behaviour of asphaltenes and other surface active materials in crude oil. Langmuir troughs are excellent tools for examining the layer formation of such water insoluble surfactants. In recent publications, Brewster angle microscopy has been used to show the layer formation properties of asphaltenes and model compounds [10-12].

Case study II: Graphene oxide sheets at interfaces

Chemical exfoliation of graphite is recognized as one of the most potential methods for producing graphene in industrial scale. The result of the exfoliation process is graphene oxide, which is known to disperse well in water due to its ionizable $-\text{COOH}$ groups. However, the basal plane of graphene is essentially a network of hydrophobic benzene rings. In the following study, the properties of graphene oxide were investigated by examining the amphiphilic nature of the molecule in a Langmuir trough. The full study was published in *Journal of American Chemical Society* 2010, 132, pp 8180 - 8186 by Kim et al [8].

Methods

Synthesized graphene oxide was examined using a Langmuir trough and Brewster angle microscope from NIMA Technology. For the CO_2 flotation experiment, graphene oxide was dispersed in carbonated water. The concentration of the solution was optimized for visual observation of the floating graphene oxide sheets.

Results and Discussion

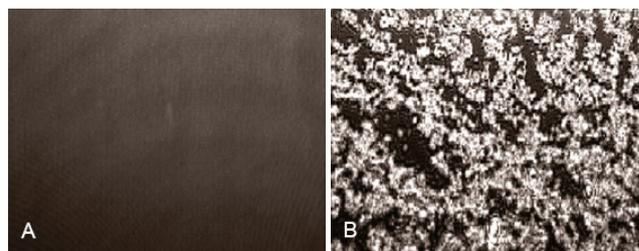

The authors examined the surface activity of graphene oxide using Brewster angle microscopy. If graphene oxide is surface active, the water surface should be covered by a layer of graphene oxide sheets. Figure 4A displays the in situ BAM image of a freshly prepared graphene oxide - water solution.

The image reveals very little surface-active material. After a few hours, graphene oxide sheets started to appear. This was attributed to slow diffusion of micrometer-sized graphene oxide sheets.

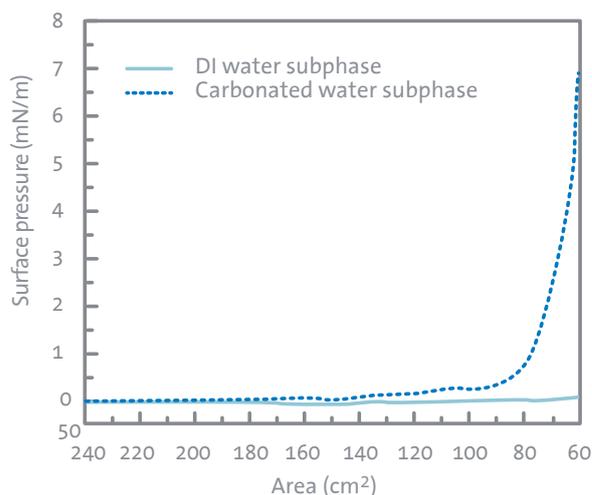

To accelerate the migration of graphene oxide to the surface, the authors designed a flotation process using carbonated water. In the process, the graphene oxide sheets adhered on to the rising CO_2 bubbles and were transported to the air-water interface. To facilitate the observation, the floating materials were concentrated by compressing the barriers in a Langmuir trough. Figure 5 presents the isotherms of graphene oxide without the flotation and graphene oxide with flotation. It can be seen that the flotation increased the surface pressure. At the same time, the Brewster angle microscopy image (Figure 4B) showed a large amount of material on the surface after the flotation process.

Conclusion

Langmuir isotherms and Brewster angle microscopy can be used to examine the properties and observe the formation of graphene oxide sheets at air-water interfaces. The study shows how mono-layer imaging can be used to improve solution processing and to help finding the optimal deposition parameters for graphene oxide materials.

Case study III: Structure of asphaltene model compounds

Asphaltenes, a class of compounds in crude oil, are known to stabilize emulsions by forming elastic interfacial films. Despite the ongoing research regarding the structure and functional groups of these polyaromatic hydrocarbons, the exact chemical composition remains unknown. In the study presented below, the interfacial activity and Langmuir film formation of model asphaltene compounds were examined using a Langmuir trough and Brewster angle microscopy. The full study was published in *Langmuir* 2008, 24, pp 8742-8751 by Nordgård et al [10].

Methods

Highly pure model asphaltene compounds were synthesized and dissolved in toluene or chloroform. The interfacial tension between the oil and water phases was measured using a pendant drop method. The surface pressure - area isotherms were recorded using a Langmuir trough. To visualize the film morphology, a Brewster angle microscope was used.

Results and Discussion

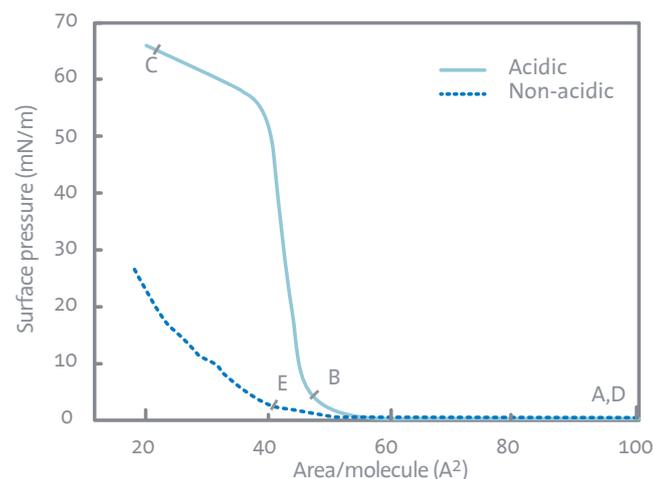

The interfacial tension measurements showed that all acidic model compounds were highly surface active while a non-acidic molecule showed only little surface activity. The Langmuir isotherms of an acidic compound and a non-acidic compound are presented in Figure 6. It can be seen that the highly surface active acidic compound was able to form a nice isotherm while the less active non-acidic molecule did not form an isotherm.

By calculating the molecular areas based on the compound structures the authors concluded that the acidic molecules were most likely arranged head-on (normal) to the water subphase surface, while the non-acidic compounds were most likely arranged flat-on (parallel) to the water subphase surface. In the head-on configuration, the molecules were able to pack efficiently and form highly organized Langmuir films. In the flat-on configuration, the non-acidic compounds were most likely arranged as stacks.

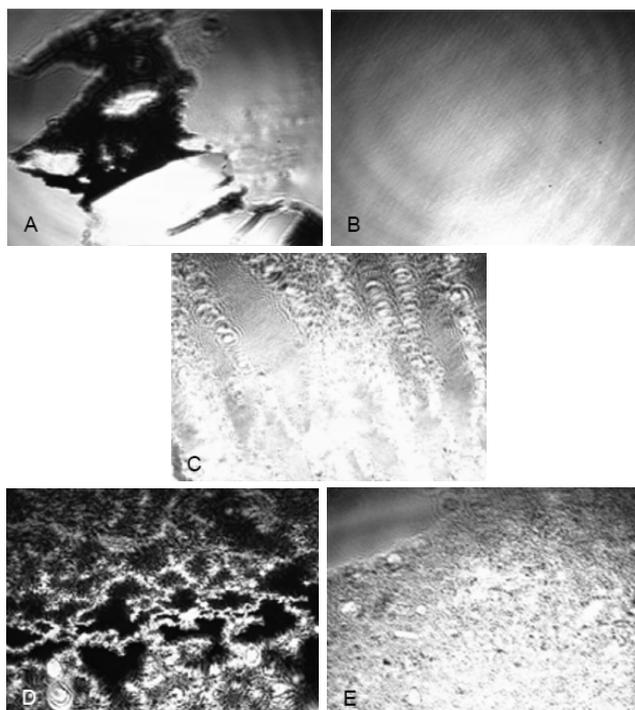

The stability of the films was further investigated using Brewster angle microscopy. Figure 7 A-C shows images taken upon compression of an acidic compound and 7 D-E of a non-acidic compound. The images correspond to the points in the isotherms marked A-E in Figure 6. In 7 A-C, a highly compressible area with condensed areas (bright) and gaseous areas (dark) is seen at low surface pressures, which turns into a smooth condensed phase when the surface pressure increases. After the collapse pressure, the film shows a "crystalline" pattern indicating multilayers. In 7 D-E, no smooth monolayer was observed.

Conclusion

Langmuir isotherm experiments show that the presence of acidic groups in asphaltene molecules is crucial for their film forming properties and interfacial activity. The packing morphology was further examined using a Brewster angle microscope. The study shows how Brewster angle microscopy can be used to correlate the structural properties and different phase transitions of Langmuir monolayers at air-water interfaces.

BAM images of a non-acidic asphaltene model compound D) before compression and E) and at 2 mN/m. With permission from Langmuir 2008, 24(16), pp 8742-8751. Copyright 2008 American Chemical Society.

Summary

Brewster angle microscopy has been shown to be a valuable method to visualize layer formation of monolayers in various application areas. Especially in LB deposition, BAM technology can help in showing the layer quality prior to deposition. KSV NIMA offers the KSV NIMA MicroBAM Brewster Angle Microscope.
